SRGP for ANSI-C (v1.0)

David Frederick Sklar

The Simple Raster Graphics Package is composed of a library of functions, and a header file ("srgp.h") that defines custom data types and constants, and which prototypes all SRGP routines. This paper is a complete but *extremely terse* description of the ANSI-C SRGP binding — this is not a tutorial. If you are new to SRGP, you must read Chapter 2 of *Computer Graphics — Principles and Practice* (Foley, van Dam, Feiner, and Hughes, Addison-Wesley, 1990).

0 Contrast with Textbook Specification

Chapter 3 of the textbook is an academic study of the issues involved in implementing any raster graphics package; it is *not* a description of the actual internal workings of any particular SRGP implementation. SRGP has been implemented on several major types of hardware platforms, and in all cases, low-level graphics utilities (QuickDraw on the Mac, X11 on workstations, and MetaGraphics on the PC) were used. Because the authors of SRGP were not involved in the implementation of the software actually drawing the primitives, there is no pixel-level compatibility between SRGP applications running on different platforms. Fortunately, the inconsistency in appearance will be typically noticeable only for extreme values for attributes (very thick primitives, rare combinations of write mode and pen/fill style, etc.).

The textbook spec did not discuss how SRGP would work in a windowing environment. This document describes how the windowing environment affects SRGP, and introduces a few new routines addressing window-specific problems.

The textbook's description of locator echo included "no echo" as an option available to the application. However, it was determined that an invisible cursor is frustrating to users of a multi-window system. The "no echo" option is thus honored only by the PC version of SRGP.

The textbook (page 33) claims that the colors black and white are 1 and 0, respectively, at all times. This is true for all devices having color tables, but it is sometimes false for monochrome systems that are designed for white-on-black display.

The textbook did not describe methods for loading bitmap and pixmap patterns into the respective pattern tables, for loading fonts into the font table, and for loading entries in the color table. See sections 3.1 and 3.3 of this document.

There are now "deluxe" versions of the measure records for each input device. These should be used when timestamps and modifier-key chords are needed.

The textbook specifies the size of the screen canvas cannot be changed by the application. That is no longer the case.

1 States of the System

SRGP must be enabled before use, and disabled after use.

```
void SRGP_begin (char *name, int width, int height, int planes,
                 boolean enable_trace);
```

The window which will represent canvas #0 (the SRGP screen-canvas) is created; its initial size is determined by the values of the second and third parameters. The first parameter specifies a name for the application. The fifth parameter specifies the initial status of the tracing feature, which is described later in this section.

The fourth parameter is meaningful only on a display supporting color. It specifies how many planes of the color table should be reserved for SRGP's use; i.e., it places an upper bound on the number of colors that may be displayed simultaneously in the SRGP window. (The upper bound is 2^p colors, where p is the number of planes.) The fourth parameter is ignored when the program is run on a bilevel display.

If the program is being run on a color display, and you send the special value "0" as the fourth parameter, SRGP will take over the entire color table, giving your application color support as rich as the hardware can offer. (After initializing SRGP, you can inquire the "canvas depth" to determine how many planes are available.) The disadvantage: it will be impossible for the user to simultaneously see the SRGP window's proper coloring and the other clients' windows' proper coloring. Thus, you should request "0" planes only when your application truly needs full control of the color table.

If you request more planes than available, all available planes are allocated, just as if you requested "0" planes. Inquiry is thus your only way of determining exactly how many planes are available.

```
void SRGP_tracing (boolean);
```

When tracing is enabled, a message is sent to a logging file ('`SRGPlogfile`' in the current directory) each time the application calls an SRGP function; the message includes echoing of key parameters. **IMPORTANT:** Calls to some of the input functions are NOT traced; see section 5 for details. See section 7 for more information on execution with tracing.

The initial status of tracing is set when the application calls `SRGP_begin`, but it may be changed at any time via a call to `SRGP_tracing`.

```
void SRGP_allowResize (boolean);
```

By default, the screen-canvas window cannot be resized by the user. It is advisable that applications live with this restriction. The rare application that needs to allow resizing can use this routine. It is important to note that various artifacts occur when the user actually does take advantage of this freedom and perform a resize:

1) The window is cleared to color 0; any information that was on the screen just before the resize is lost.
2) The clip rectangle attribute is **not** changed automatically; the application must be responsible for changing it if necessary.

Obviously, an application that allows resizing must be informed whenever a resize occurs, to cope with the aforementioned problems and other application-specific ones. SRGP provides a callback utility, which allows an application to provide a function to be called whenever a resize has occurred:

```
typedef int (*funcptr)();
void SRGP_registerResizeCallback (funcptr);
```

The application-provided callback function referred to by the function-pointer parameter will be called whenever a resize has occurred. The callback function will receive two integers: the new width and the new height.

```
void SRGP_changeScreenCanvasSize (int newwidth, int newheight);
```

This routine allows the application to modify the size of the screen canvas. As a side-effect, the resize-callback function (if any) is called, just as if the user had requested the resize.

```
void SRGP_enableSynchronous (void);
```

Allows you to enable X's synchronous mode, a useful mode for debugging. The mode is discussed rigorously in section 3, and again in section 7.

```
void SRGP_end (void);
```

The screen-canvas window is deleted, and the logging file is closed.

2 Canvases

SRGP procedures operate on *canvases*, a canvas being a 2D array of pixels (a virtual frame-buffer), whose depth is the number of planes requested by the application (via the fourth parameter to `SRGP_begin`).

Each canvas has its own local coordinate system. The origin $(0, 0)$ for the local coordinate system is the lower-left corner of the canvas, with the X-coordinate increasing to the right, and the Y-coordinate increasing towards the top. The coordinates passed to all primitive-generation procedures are in terms of the local coordinate system of the *currently-active canvas*.

At any given time, one canvas is active: it is the canvas being modified. Associated with each canvas is a group of *attributes* which affect all drawing into that canvas. Modification of these attributes is only possible when the corresponding canvas is currently active. When a canvas is created, its attribute group is initialized to standard default values.

Each canvas is identified by a unique integer *canvas index*. When SRGP is enabled, one canvas already exists and is active: the *screen canvas*, having index 0, whose height and width are determined from the parameters to `SRGP_begin`. The screen canvas is the only canvas which is *ever* visible. No more than `MAX_CANVAS_INDEX`+1 canvases (including the screen) may be extant simultaneously.

Canvases may be manipulated by the following procedures:

```
typedef int canvasID;
canvasID SRGP_createCanvas (int width, int height);
```

An invisible canvas of the specified dimensions is created and its unique index is returned. The new canvas' local-coordinate-system origin $(0, 0)$ forms the lower-left corner. $(width - 1, height - 1)$ forms the upper-right corner. The pixels of a canvas initially store color index 0. Once a canvas is created, it can not be resized. (The screen canvas is an exception, but it can only be resized by the user, not by the application.) Upon return, the new canvas (and its corresponding attribute group) are active. If a new canvas cannot be created, 0 is returned.

`void SRGP_deleteCanvas (canvasID);`

No canvas may be deleted while it is active. Moreover, the screen canvas cannot be deleted with this routine.

`void SRGP_useCanvas (canvasID);`

The specified canvas becomes active. Primitives created subsequently are drawn in this canvas, and attributes set subsequently modify this canvas' attribute group.

3 Output

3.1 color

SRGP maintains a lookup table (LUT) that maps *color indices* (which are integers, used to index into the LUT) to actual colors. The number of entries available in the lookup table is based on the number of planes allocated for the application's use (via the fourth parameter to `SRGP_begin`). The number of planes available can be inquired via:

```
int SRGP_inquireCanvasDepth (void);
```

The legal color indices are numbers between (inclusive) 0 and $2^{canvasdepth} - 1$. The use of color indices beyond that range are clamped to $2^{canvasdepth} - 1$. (Negative values are illegal and will cause an error.) All implementations support two colors that may be referenced using names instead of numbers: `SRGP_WHITE` and `SRGP_BLACK`.

On color nodes, `SRGP_WHITE` is 0 and `SRGP_BLACK` is 1, and they are the only initialized entries in the LUT. One should note, however, that if the first two entries of the LUT are changed by the application, the names (SRGP_BLACK and SRGP_WHITE) are no longer meaningful.

On monochrome displays, the two symbols `SRGP_BLACK` and `SRGP_WHITE` are implementation-dependent constants. Moreover, the use of a color index greater than 1 is clamped to 1 on a monochrome display.

An application may load a contiguous portion of the LUT by creating three arrays (one for red, one for blue, one for green) of *intensity values*, each value being an unsigned 16-bit integer. Intensity value 0 represents that primary's not contributing at all to the actual color, and $2^{16} - 1$ (65,535) represents that primary contributing its full glory to the actual color. Note that this method for specifying colors is machine-independent; workstations supporting only C bits per intensity value will ignore all but the C most significant bits of each intensity value.

To load `count` entries of the LUT, starting with entry `start`, create the three intensity value arrays and then call:

```
typedef unsigned short ush;
void SRGP_loadColorTable (int start, int count, ush *r, ush *g, ush *b);
```

An easy way to store "common" colors is provided by SRGP. Common colors are those colors which have been given names (like "Purple", "MediumForestGreen", and "Orange") by the X11 implementation. A complete list of the supported colors is usually found in '`/usr/lib/X11/rgb.txt`'. SRGP supports only the setting of one LUT entry at a time when using common colors:

```
void SRGP_loadCommonColor (int entry, char *colorname)
```

3.2 geometric data types

The following SRGP data types allow storage of geometric entities:

```
typedef struct {
      int x, y;
} point;

typedef struct {
      point bottom_left, top_right;
} rectangle;
```

Instances of these data types may be created using these routines:

```
point SRGP_defPoint (int x, int y);
rectangle SRGP_defRectangle (int left_x, int bottom_y, int right_x, int top_y);
```

3.3 control of the pattern and font tables

Several of the SRGP attributes are patterns to be used for filling areas and for drawing lines and frames. Two pattern tables are supported: one storing bitmaps and one storing pixmaps.

The bitmap pattern table is initialized in this way: Pattern 0 is all background, and pattern 1 is all foreground. Patterns 1 through 38 are the standard Macintosh patterns shown in Volume 1 of Chernicoff's *Macintosh Revealed,* and page I-474 of *Inside Macintosh.* Patterns 40 through 104 are greyscale patterns increasing gradually in intensity from all background (40) to all foreground (104). All other entries in the bitmap pattern table are undefined; use of an undefined pattern is a fatal error. To see an array of tiles showing the default bitmap pattern table, run the example program `show_patterns`.

Only entry 0 in the pixmap pattern table is defined, and it is simply an all-color-0 pattern.

SRGP provides two methods for changing entries in the pattern table:

- You can have SRGP load one or more patterns from a file which stores ASCII-text pattern specifications you can create using a text editor or convenient bitmap-editor programs (if available).
- You can give SRGP a pattern specification in the form of an array of numbers.

To load a bitmap pattern from a file, open the file and pass the stream to the function:

```
int SRGP_loadBitmapPatternsFromFile (FILE *stream);
```

The input may be composed of one or more pattern specifications ("specs"). Each spec must occupy exactly two lines and must match this format:

```
static char bitpat_Xy[] = {
   0x??, 0x??, 0x??, 0x??, 0x??, 0x??, 0x??, 0x??};
```

where `X` is a non-negative integer specifying the index of the entry to be set, `y` is any arbitrary garbage between the integer and the left square-brace, and `0x??` is any arbitrary byte value represented in hexadecimal. This specification format is created automatically by X's bitmap editor *bitmap*.

As a convenience, any lines beginning with '`#`' are ignored, but these comment lines must not interrupt a single two-line spec sequence. Blank unused lines are not allowed anywhere in the file.

The closing of the input stream must be performed by the caller. This function returns 1 if any problems at all occurred; since its parser makes no attempt at error recovery, it is wise to check the return value.

To load a pixmap pattern from a file, use this routine whose functionality is similar to that of the one for bitmap patterns:

```
int SRGP_loadPixmapPatternsFromFile (FILE *stream);
```

The input may be composed of one or more pattern specifications, each matching this format:

```
static int pixpat_Xy[] = {
   ?, ?, ?, ?, ?, ?, ?, ?,
   ?, ?, ?, ?, ?, ?, ?, ?,
   ?, ?, ?, ?, ?, ?, ?, ?,
   ?, ?, ?, ?, ?, ?, ?, ?,
   ?, ?, ?, ?, ?, ?, ?, ?,
   ?, ?, ?, ?, ?, ?, ?, ?,
   ?, ?, ?, ?, ?, ?, ?, ?,
   ?, ?, ?, ?, ?, ?, ?, ?};
```

In this specification, each `?` represents a decimal integer color index.

Applications generating the patterns at runtime can use these routines to set one entry at a time:

```
void SRGP_loadBitmapPattern (int pattern_id, char *data);
void SRGP_loadPixmapPattern (int pattern_id, int *data);
```

The former routine expects an array of 8 characters; the latter an array of 64 integers.

Another attribute is the font to be used for text. SRGP provides a table of fonts that may be used and modified by the application. Each entry is identified by a unique *font index* (ranging from 0 to `MAX_FONT_INDEX`). Initially, only entry #0 of the font table is defined. The application can modify the table via:

```
void SRGP_loadFont (int fontindex, char *name);
```

This function allows the application to load a font into a given entry of the table. The name of the font is simply the name of a file containing the font's description. The filename must be absolute (begin with a slash) unless the font lies in the default directory that is used by X in font searches.

3.4 control of attributes affecting output

These procedures allow control of the value of each attribute associated with the currently-active canvas.

```
typedef enum {WRITE_REPLACE, WRITE_XOR, WRITE_OR, WRITE_AND} writeModeType;
void SRGP_setWriteMode (writeModeType);
```

The write mode affects the writing of a pixel, the generation of a primitive, and the copying of a rectangular portion of a canvas. The default is `WRITE_REPLACE`.

```
void SRGP_setClipRectangle (rectangle);
```

All subsequently-created primitives and subsequent pixel-copyings are clipped to the specified rectangle. The default clipping rectangle is exactly the size of the associated canvas. It is illegal to set the clipping rectangle to a rectangle which does not lie completely within the boundaries of its associated canvas.

```
void SRGP_setFont (int font_index);
```

The application chooses from a font by giving the index (ranging from 0 to `MAX_FONT_INDEX`) into the font table. The default is 0, the only entry in the font table which is initialized when SRGP is launched.

```
void SRGP_setMarkerSize (int width_in_pixels);
```

This describes the dimensions of the imaginary square that circumscribes a marker's image.

```
typedef enum {MARKER_CIRCLE, MARKER_SQUARE, MARKER_X} markerStyleType;
void SRGP_setMarkerStyle (markerStyleType);
```

SRGP supports three different marker shapes, circle being the default.

```
typedef enum {CONTINUOUS, DASHED, DOTTED, DOT_DASHED} lineStyleType;
void SRGP_setLineStyle (lineStyleType);
void SRGP_setLineWidth (int width_in_pixels);
```

The default line style is continuous, default line width is 1.

```
void SRGP_setColor (int color_index);
```

This sets the foreground (drawing) color to the color that is stored at the given entry in the LUT; the default is 1.

```
void SRGP_setBackgroundColor (int color_index);
```

Default is 0. The background color is used to color the pixels denoted by 0 values in opaque bitmap pattern fills.

```
void SRGP_setPlaneMask (int bitmask);
```

The default plane mask is all 1's. The lowest p bits of the integer bitmask are used, where p is the number of planes allocated for the application.

```
typedef enum {
  SOLID, BITMAP_PATTERN_OPAQUE, BITMAP_PATTERN_TRANSPARENT, PIXMAP_PATTERN}
    drawStyle;
void SRGP_setFillStyle (drawStyle);
void SRGP_setPenStyle (drawStyle);
```

Fill style affects filled primitives; pen style affects outlined (framed) primitives or lines. Text is not affected by either of these attributes. Default is `SOLID`.

```
void SRGP_setFillBitmapPattern (int pattern_index);
void SRGP_setFillPixmapPattern (int pattern_index);
void SRGP_setPenBitmapPattern (int pattern_index);
void SRGP_setPenPixmapPattern (int pattern_index);
```

Denotes the entry in the appropriate pattern table which is to be used when the fill or pen style is not `SOLID`.

The entire set of attributes may be set to a previously-stored group of values using the function described next. Later in this reference is described the function (`SRGP_inquireAttributes`) that allows inquiry of the current attribute group.

```
typedef struct ... attribute_group;   /* see srgppublic.h for details */
void SRGP_setAttributes (attribute_group*);
```

The parameter's value should have been obtained from a previous call to `SRGP_inquireAttributes`.

3.5 generation of primitives

The functions described in this section perform drawing in the currently active canvas. For each primitive generator described, the list of attributes affecting its operation is presented.

An ellipse is specified in terms of the rectangle within which it is inscribed. Polygons, rectangles, and ellipses may be generated as *framed* or *filled*. A filled primitive is all-interior — the frame is not displayed.

WARNING: because SRGP by default uses X's asynchronous mode, a call to an output primitive routine may not produce an image for an arbitrary length of time, or may not produce an image at all! This is because in asynchronous mode, X commands are buffered, being actually sent only when/if the buffer gets full or when/if your program attempts to perform any kind of graphical input. If your program often uses SRGP input devices, this should not be a problem; but, if your application is output-only or has sleeps or long pauses not related to waiting for input, you must explicitly flush the X buffer at appropriate times, using this function:

```
void SRGP_refresh (void);
```

Alternatively, you can place X in synchronous mode using the routine described in section 1. This guarantees a buffer flush after each application-level call to SRGP output routines, but at great performance cost.

```
void SRGP_point (point);
void SRGP_pointCoord (int x, int y);
```

Current write mode, foreground color, and plane mask apply.

```
void SRGP_marker (point)
void SRGP_markerCoord (int x, int y)
```

Current marker style, marker size, write mode, foreground color, and plane mask apply.

```
void SRGP_line (point pt1, point pt2);
void SRGP_lineCoord (int x1, int y1,  int x2, int y2);

void SRGP_rectangle (rectangle);
void SRGP_rectanglePt (point lower_left, point upper_right);
void SRGP_rectangleCoord (int left_x, int lower_y,  int right_x, int upper_y);
```

Current write mode, plane mask, colors, line width, line style, and pen style apply.

```
void SRGP_polyPoint (int vert_count, point *vertices);
void SRGP_polyMarker (int vert_count, point *vertices);
void SRGP_polyLine (int vert_count, point *vertices);
void SRGP_polygon (int vert_count, point *vertices);

void SRGP_polyPointCoord (int vert_count, int *x_coords, int *y_coords);
void SRGP_polyMarkerCoord (int vert_count, int *x_coords, int *y_coords);
void SRGP_polyLineCoord (int vert_count, int *x_coords, int *y_coords);
void SRGP_polygonCoord (int vert_count, int *x_coords, int *y_coords);
```

Current write mode, plane mask, colors, line width, line style, and pen style apply. `SRGP_polygon(Coord)` automatically connects the first and last vertices to form a closed polygon. Lists of vertices and coordinates are limited in size to `MAX_POINTLIST_SIZE`.

```
void SRGP_ellipse (rectangle bounds);
void SRGP_ellipseArc (rectangle bounds, double startangle, double endangle);
```

Current write mode, plane mask, colors, line width, line style, and pen style apply. An arc extends counterclockwise from the start angle to the end angle. Angles are in rectangular degrees and must lie between 0 and 360, with 0 degrees being a horizontal ray extending towards positive infinity.

```
void SRGP_fillPolygon (int vert_count, point *vertices);
void SRGP_fillPolygonCoord (int vert_count, int *x_coords, int *y_coords);
void SRGP_fillEllipse (rectangle);
void SRGP_fillEllipseArc (rectangle bounds, double startangle, double endangle);
void SRGP_fillRectangle (rectangle);
void SRGP_fillRectanglePt (point lower_left, point upper_right);
void SRGP_fillRectangleCoord (int left_x, int lower_y, int right_x, int upper_y);
```

Current write mode, plane mask, colors, and fill style apply.

```
void SRGP_text (point origin, char *str);
```

Current write mode, plane mask, foreground color, and font apply. The origin marks the leftmost point to be affected by the text, and marks the horizontal baseline for the text, under which only the text's characters' descenders will appear.

3.6 audio output

```
void SRGP_beep (void);
```

4 The copyPixel Procedure

This procedure allows a portion of a canvas to be copied into another part of itself or into another canvas. See the textbook for more information on this powerful feature.

```
void SRGP_copyPixel (canvasID source_canvas, rectangle source_rect,
                     point dest_corner);
```

The copying operation is composed of two parts. First, a *copy* of a rectangular portion of a canvas is created. Then, the copy is *placed* somewhere within the currently-active canvas. (The currently-active canvas may or may not also be the canvas providing the source of the copy.)

`dest_corner` describes the lower-left corner of the destination rectangle (lying inside the currently-active canvas) having the same size as `source_rect`.

Only the rectangular portion of `source_rect` which lies within the boundaries of the source canvas is copied. The placement operation is affected by the current clipping-rectangle and write-mode.

5 Input

An application program obtains input from an operator by controlling a set of *logical input devices*, each representing a unique input technique. Each device may be placed in a number of different *input modes*, each representing a unique type of interaction with the input device.

5.1 properties of input devices

Each input device is described in terms of these information: a *measure*, a *trigger set*, and a set of *attributes*.

The *measure* of an input device is the value currently associated with the device.

The *trigger* of an an input device is the action which indicates a significant moment associated with the device.

The *attributes* of an input device are the parameters of the device which are under application-control, primarily the echo characteristics.

At any given time, each device is either *active* or *inactive*. The process of *activation* places a device into an active state; the process of *deactivation* places it into an inactive state. Zero or more devices may be simultaneously active.

5.2 input modes

There are three modes in which input devices operate. (Initially, each device is inactive.) The modes' names are listed below, accompanied by a description:

`INACTIVE` When device α is inactive, no events are posted concerning it, and its measure is not available to the application.

`SAMPLE` When device α is in Sample mode, it is active. The application may call '`SRGP_sample`α' to immediately obtain the measure of input device α. The firings of α-triggers do not have any effects.

`EVENT` When device α is in Event mode, it is active. The firing of an α-trigger causes an *input report* (containing the measure of the device at the time of the firing) to be appended to the *input queue*.

The following function allows control of the input modes and echoing for all input devices:

```
typedef enum {NO_DEVICE, LOCATOR, KEYBOARD} inputDevice;
typedef enum {INACTIVE, SAMPLE, EVENT} inputMode;
void SRGP_setInputMode (inputDevice, inputMode);
```

The specified input device is placed in the specified mode. Whenever device α's mode is changed from Inactive to either Sample or Event, the device is *activated*: its measure is initialized (to a static default initial value, or to a value specified by the application while the device was inactive) and echoing begins. When α's mode is set to Event, queueing of the device's event reports is enabled as well. When α's mode is changed from Event, all queued events for that device are discarded.

When α's mode is set to Inactive, the device is *deactivated*: trigger firings from the device are ignored and echoing is disabled.

5.3 input devices

The SRGP input devices are described in this section.

`LOCATOR` The measure of the Locator device incorporates a position expressed in the coordinate system of the screen canvas, a chord giving the status of the mouse buttons, and the number of the button which most recently experienced a transition. The button-chord array is indexed using three constants: `LEFT_BUTTON`, `MIDDLE_BUTTON`, and `RIGHT_BUTTON`.

The *button-mask* attribute of this device determines which of the buttons are of interest when the device is active in Event mode: only buttons specified in this mask can trigger an event.

```
typedef enum {UP, DOWN} buttonStatus;
typedef struct {
   point position;
   buttonStatus button_chord[3];
   int button_of_last_transition;
} locator_measure;
```

The "deluxe" version of the locator measure includes a chord giving the status of three primary modifier keys at the time of the last button transition, and a timestamp structure. The modifier chord array is indexed via `SHIFT`, `CONTROL`, and `META`. (Warning: the physical key to which the META modifier maps varies from system to system; moreover, some window manager setups will swallow button presses modified by these keys, and thus applications that rely on modifier keys lose some portability.) The timestamp specifies the time at which the most recent *change* to the measure occurred — i.e., successive sampling of a non-moving locator produces a "constant" timestamp.

```
typedef struct {
   int seconds;                          duration since application launch
   int ticks;                                 a tick is 1/60th second
} srgp_timestamp;

typedef struct {
   point position;
   buttonStatus button_chord[3];
   int button_of_last_transition;
   buttonStatus modifier_chord[3];                  status at last transition
   srgp_timestamp timestamp;
} deluxe_locator_measure;
```

`KEYBOARD` The measure of this device is a character string, storing either a single ASCII character code or a sequence of printable characters.

The "deluxe" version of the measure includes the modifier chord, a timestamp, and a locator position:

```
typedef struct {
   char *buffer;                         ptr to space allocated by application
   int buffer_length;                                set by application
   buttonStatus modifier_chord[3];
   point position;
   srgp_timestamp timestamp;
} deluxe_keyboard_measure;
```

The *processing-mode* attribute of this device determines which of the two meanings is given to the measure of the device:

RAW: When a key is hit, the measure stores a string of length 1 whose single element is the ASCII character code of the key hit (taking into account the status of the shift and control modifier keys) and a trigger-firing occurs. The modifier chord shows the status of the modifiers when the key was hit. No echo occurs in RAW mode.

EDIT: (the default) When a key representing a printable character is hit and the string is not yet full, the character is appended to the string. When the backspace key is hit, the last character of the string is deleted. When return is hit, an event is sent (representing the full value of the string) and the measure is set to the null string. In EDIT mode, the modifier chord is not maintained and should be ignored.

C programmers should take care to allocate a buffer large enough to include the null character that terminates the string measure. For example, two bytes are needed to store a RAW-mode measure.

5.4 control of attributes

The following procedures set the attributes for input devices. Attributes may be set at any time, regardless of whether the device is active or inactive.

```
void SRGP_setLocatorButtonMask (int value);
```

The value should be 0 or an OR combination of one or more of the following defined constants: `LEFT_BUTTON_MASK`, `MIDDLE_BUTTON_MASK`, and `RIGHT_BUTTON_MASK`. Initially the value is `LEFT_BUTTON_MASK`: meaning only the left button (which is the only button on a 1-button mouse) generates events.

```
SRGP_setLocatorEchoType (int value);  /* CURSOR, RUBBER_LINE, or RUBBER_RECT */
```

An application can choose to have just the cursor, or to also have a rubber-primitive (anchored at a fixed point with the other end of the primitive following the cursor's movement). Note: the value `NO_ECHO` is also accepted, but it is ignored on all platforms except the IBM PC.

SRGP provides a cursor table whose 0th entry is initialized to an arrow; all other entries are unusable until loaded.

```
void SRGP_loadCursorTable (int cursor_index, int shape);
/* shape: any constant defined in <X11/cursorfont.h> */
```

Legal cursor indices are numbers between 0 and `MAX_CURSOR_INDEX`, inclusive. The shape may be any constant defined in the "cursorfont.h" file that is provided by X11.

The attributes for the locator's echo are set via:

```
void SRGP_setLocatorEchoCursorShape (int cursor_index);
void SRGP_setLocatorEchoRubberAnchor (point position);
```

The keyboard's attributes are set via:

```
typedef enum {EDIT, RAW} keyboardMode;
void SRGP_setKeyboardProcessingMode (keyboardMode);
void SRGP_setKeyboardEchoColor (int color_index);
void SRGP_setKeyboardEchoFont (int font_index);
void SRGP_setKeyboardEchoOrigin (point position);
```

Keyboard echo attributes are only meaningful when the keyboard is active in EDIT processing mode. Setting the keyboard's processing mode (default EDIT) clears the keyboard's measure as a side-effect.

5.5 control of measures

The measure of a device may be changed by the application at any time. If the change is performed while the device is active, the measure immediately changes, as does as echoing concerning the device. If it is done while the device is inactive, the specified measure is used to initialize the device's measure the next time it is activated. NOTE: the button-related fields of the locator measure may not be changed by the application.

```
void SRGP_setLocatorMeasure (point value);
void SRGP_setKeyboardMeasure (char *value);
```

5.6 sample procedures

The involved input device must be in SAMPLE mode. Each function places in the provided place the current measure of the corresponding device. Calls to these routines are NOT traced.

The `SRGP_sampleKeyboard` function copies the keyboard measure into the given character-array buffer of size `buffer_length`. If the current keyboard measure is longer than (*bufferlength*−1) bytes, it is truncated. Similarly, the keyboard-measure structure sent to `SRGP_sampleDeluxeKeyboard` must have pre-set values for its `buffer` and `buffer_length` fields.

```
void SRGP_sampleLocator (locator_measure *measure);
void SRGP_sampleKeyboard (char *buffer, int buffer_length);
void SRGP_sampleDeluxeLocator (deluxe_locator_measure *measure);
void SRGP_sampleDeluxeKeyboard (deluxe_keyboard_measure *measure);
```

5.7 event procedures

Calls to these functions are NOT traced.

```
inputDevice SRGP_waitEvent (int maximum_wait_time);
```

If, upon entry, the event queue is not empty, the procedure exits immediately, identifying the event report at the head of the queue and removing the report from the queue. Otherwise, the application enters a wait state, which is exited upon the first occurrence of a trigger-firing from any device which is currently in EVENT mode. The wait state never lasts for more than the number of ticks (1/60 seconds) given in the `maximum_wait_time` parameter (which, when negative, represents infinity). An application can "poll" the queue (avoiding a wait state) by specifying "0" as the maximum wait time.

The return value identifies the device causing the event. The special value `NO_DEVICE` is returned when the procedure exits due to timeout.

When an application discovers that an input event (not a timeout) caused the return of `SRGP_waitEvent`, it may obtain the data associated with the involved event by using the appropriate "get" function, whose parameters and return values mimic those of the sample functions:

```
void SRGP_getLocator (locator_measure *measure);
void SRGP_getKeyboard (char *measure, int buffer_length);
void SRGP_getDeluxeLocator (deluxe_locator_measure *measure);
void SRGP_getDeluxeKeyboard (deluxe_keyboard_measure *measure);
```

6 Inquiry

NOTE: Calls to these routines are NOT traced.

```
void SRGP_inquireAttributes (attribute_group *group);
```

The current states of all attributes are copied into the provided group structure. For information on the names of the fields in the structure, see '`srgppublic.h`'.

```
canvasID SRGP_inquireActiveCanvas (void);
```

This function allows inquiry of the ID of the currently-active canvas.

```
rectangle SRGP_inquireCanvasExtent (canvasID);
void SRGP_inquireCanvasSize (canvasID, int *width, int *height);
```

Two functions allowing inquiry of the size of a canvas.

```
int SRGP_inquireCanvasDepth (void);
```

Returns the number of planes available in all canvases.

```
void SRGP_inquireTextExtent (char *str, int *width, int *ascent, int *descent);
```

This procedure allows inquiry of the rectangular extent which would be covered by the output of the given character string with the current font attribute.

7 Control of Table Sizes

The tables that store patterns, fonts, etc. have default sizes that in many cases are acceptable. You may, however, choose to reduce the size of a table to save memory (if you're working on a Mac Plus, for instance) or increase the size of a table if you need more entries. You may change the size of a table *only before* SRGP is initialized!

```
void SRGP_setMaxCanvasIndex (int i);
void SRGP_setMaxPatternIndex (int i);
void SRGP_setMaxCursorIndex (int i);
void SRGP_setMaxFontIndex (int i);
void SRGP_setMaxPointlistSize (int i);
```

See '`srgp_sphigs.h`' for the defaults for these sizes. NOTE: Do not reduce the size of the pattern table!

8 Diagnostics, Debugging, and Optimization

SRGP offers two features that aid the developer in debugging an application. Both of these features may be disabled or enabled by the programmer and even by the user at run-time, in order to optimize the execution.

The first feature is tracing. When enabled, each call to an SRGP routine (except a few input-related routines) produces a detailed message in a log file. A parameter to `SRGP_begin()` controls the initial state of tracing; calls to `SRGP_tracing` can be used to control the state during runtime. Early test runs of an application should always be performed with tracing enabled. For more details on tracing, see Section 1.

The second feature is parameter verification. All SRGP routines perform verification of all parameters (except those that are pointers to an array or structure) before they commence operation. All errors are fatal and produce a crash with a detailed error message. Only when a program is fully debugged should optimization efforts include disabling parameter verfication! You may permanently disable verification and tracing via:

```
void SRGP_disableDebugAids (void);
```

If your application crashes due to an X server error or in the scope of an SRGP routine, there are two possibilities (assuming the X server is not at fault):

- You passed invalid data to an SRGP routine, via a parameter that is not subject to SRGP's verification. For example, SRGP assumes the sanity of pointers it receives (e.g., pointer to a vertex list).
- There is a bug in SRGP. To help the system administrator locate or report the bug, edit the application to use the following sequence to initialize, and run the program with tracing and parameter verification enabled:

```
SRGP_beginWithDebug (name, w, h, p, TRUE);
SRGP_enableSynchronous();
```

About SRGP's diagnostics: There are two types of run-time errors. The first type is parameter-verification errors; the verification can be turned off as mentioned earlier. The second type occurs when a problem unrelated to bad input occurs, like running out of memory when attempting to allocate a canvas. All errors – of both types – are considered fatal by default, and cause a crash after displaying an informative message to the user. Some programmers might wish to make all errors be non-fatal, so program execution can continue (with suitable recovery algorithms, of course). The following routine can be used to choose between fatal and non-fatal error handling:

```
typedef enum {FATAL_ERRORS, NON_FATAL_ERRORS} errorHandlingMode;
void SRGP_setErrorHandlingMode (errorHandlingMode);
```

When an error is detected by SRGP while the mode is `NON_FATAL_ERRORS`, no message is issued to the user; rather, a global variable is set to a positive integer that represents the error:

```
#include "srgp_errtypes.h"
extern int SRGP_errorOccurred;
```

The header file contains symbolic constants mapping the integers to error types. The global variable is never reset to 0 by SRGP; the application is responsible for examining and resetting it. Obviously, non-fatal mode should be used with great care, and only late in an application's development.

9 Miscellaneous (Hints, Caveats, etc.)

An SRGP application cannot control multiple windows: only canvas #0 is represented by a visible window.

Keep the difference between synchronous and asynchronous modes in mind: if a brief application produces no output, it may be because the X command buffer is not being flushed. For more information, see section 3.4.

On color machines, if the SRGP application requests full color support (by passing 0 as the fourth parameter to `SRGP_begin`), the windows of clients other than the SRGP application will not show their "true" colors whenever the cursor lies within the SRGP window; likewise, the SRGP window will show false colors whenever the cursor lies outside its extent. This can be disconcerting, and an application that does not need full use of the color table should instead reserve a subpart of the color table by sending a positive integer to `SRGP_begin`. (Note: if your application does not call `SRGP_waitEvent` often enough, SRGP will not be notified of the cursor's location, and thus it may not be able to restore true colors when the cursor enters the SRGP window.)

Note that color indices are integers (rather than unsigned longs, as in X). This means that in the rare event that one is using a machine with a 32-bit deep framebuffer but with only 16-bit integers, the full set of LUT entries will not be available.

Most machines support X's backing-store feature; on these machines, SRGP refreshes its window whenever any part that was previously covered is re-exposed, or whenever it is de-iconized. On other machines, the graphic information in the window is volatile and is lost whenever it is covered or iconized.
